Abstract

The estimated accuracy of a classifier is a random quantity with variability. A common practice in supervised machine learning, is thus to test if the estimated accuracy is significantly better than chance level. This method of signal detection is particularly popular in neuroimaging and genetics. We provide evidence that using a classifier's accuracy as a test statistic can be an underpowered strategy for finding differences between populations, compared to a bona-fide statistical test. It is also computationally more demanding than a statistical test. Via simulation, we compare test statistics that are based on classification accuracy, to others based on multivariate test statistics. We find that probability of detecting differences between two distributions is lower for accuracy based statistics. We examine several candidate causes for the low power of accuracy tests. These causes include: the discrete nature of the accuracy test statistic, the type of signal accuracy tests are designed to detect, their inefficient use of the data, and their regularization. When the purposes of the analysis is not signal detection, but rather, the evaluation of a particular classifier, we suggest several improvements to increase power. In particular, to replace V-fold cross validation with the Leave-One-Out Bootstrap.

Index Terms

signal-detection, multivariate-testing, supervised-learning, hypothesis-testing, high-dimension.

I. INTRODUCTION

Many neuroscientists and geneticists detect signal by fitting a classifier and testing whether it's prediction accuracy is better than chance. The workflow consists of fitting a classifier, estimating its predictive accuracy using cross validation, and test the hypothesis that this accuracy can be attributed to chance alone. This general idea has been promoted by [1], [2], [3], [4]. Examples in the genetics literature include [5], [6], [7], [8], [9], [10], [11]. Other examples include speaker verification [12], text classification [13], [4], distinguishing between facial expressions [4], data integration [12], record linkage in databases systems [12], [14], [15], optical character recognition [16], multimedia [17], and functional data analysis [14].

Manuscript received April 19, 2005; revised August 26, 2015.

Examples in the neuroscientific literature, which is our motivating use-case, include [18], [19], [20], [21], [22], and especially the recently popularized *multivariate pattern analysis* (MVPA) framework in [23].

To fix ideas, we will adhere to a concrete example. In [24], the authors seek to detect brain regions that encode differences between vocal and non-vocal stimuli. Following the MVPA workflow, the localization problem is cast as a supervised learning problem: if the type of the stimulus can be predicted from the brain’s activation pattern significantly better than chance, then a region is declared to encode vocal/non-vocal information. We call this an *accuracy test*, because it uses the prediction accuracy as a test statistic.

This same signal detection task can also be approached as a multivariate *two-group* test. Inferring that a region encodes vocal/non-vocal information, is essentially inferring that the spatial distribution of brain activations is different given a vocal/non-vocal stimulus. As put in [19]:

... the problem of deciding whether the classifier learned to discriminate the classes can be subsumed into the more general question as to whether there is evidence that the underlying distributions of each class are equal or not.

A practitioner may thus approach the signal detection problem with a two-group hypothesis test. Multivariate two-groups hypothesis-tests may be divided into tests for equality of location (i.e. means), and two-sample goodness of fit tests (i.e., equality of the two whole distribution, GOF in short). The former generalizing the t-test, and the latter (roughly) generalizing Kolmogorov-Smirnov’s test.

Crucially for our applications, we will assume that the number of samples is in the order of the dimension of each sample, if not smaller. In the statistical literature this is known as a *high-dimensional* problem. We emphasize that by high-dimension it is not necessarily implied that the sample is large, even if it is often the case. In our motivating example it means that the size of the brain’s region of interest is large compared to the number of subjects in the experiment. It is thus a high-dim–small-sample problem.

In a seminal contribution, [25] noted that in-high dimension, multivariate tests tend to be low powered unless some regularization is involved. Since then, many high-dimensional tests have been proposed. These can be classified along the following lines:[TODO: verify references]

- **High-dim GOF:** Tests that seek for any difference between two distributions, such as [14], [26], [12].
- **High-dim location test for sparse shift:** Tests the seek for a sparse shift in mean vectors such as [27], [28].
- **High-dim location test for dense shift:** Tests the seek for a dense shift in mean vectors such as [29], [25], [30], [31], [32], [33], [34], [35], [36], [37], [38].
- **High-dim location test for shift with unknown sparsity:** Tests the seek for a shift in mean vectors, but adapt to the unknown sparsity, such as [39], [40], [41].

At this point, it becomes unclear which test is preferable, in particular for genetics and neuroimaging? In this manuscript, we do not provide a full answer to the matter. Instead, we merely seek to demonstrate that **accuracy tests are never optimal, compared to two-group tests**. Our recommendations to the practitioner in these high-dim problems: (i) Prefer a two-group test over an accuracy test. (ii) Appropriate regularization is crucial.

Various authors have compared accuracy tests to two-group tests, often with contradicting conclusions. In [11] for instance, authors find that an accuracy test based on a tree predictor is preferable over a two-group test. Their

simulated shift is sparse, so that it is no surprise that a tree-type predictors outperforms linear predictors and tests. Authors of [21] compare the kernel test of [12] to an accuracy-test based on logistic-regression. Their results are inconclusive with a slight advantage to the logistic regression. In [4], authors compare several accuracy tests to several two-group tests and conclude that an accuracy test based on a neural-net is preferable. Their argument is that the neural-net is able to learn the features that best separate the samples. Their examples, however, are low-dimensional (even if large-sample), and such feature learning is typically impossible in high-dimension.

Ramdas et al. [42] currently offer the only analytic comparison; comparing Hotelling's T^2 location test to Fisher's linear discriminant analysis (LDA) accuracy test. By comparing the rates of convergence of the power of each statistic, [42] conclude LDA and T^2 are rate equivalent. Rates, however, are only a first stage when comparing test statistics.

Asymptotic relative efficiency measures (ARE) are typically used by statisticians to compare between rate-equivalent test statistics [43]. ARE is the limiting ratio of the sample sizes required by two statistics to achieve similar power. The authors of [42] derive the asymptotic power functions of the two test statistics, with which we compute the ARE between Hotelling's T^2 (two-group) test and Fisher's LDA (accuracy) test. Theorem 14.7 of [43] relates asymptotic power functions to ARE. Using this theorem and the results of [42] we deduce that the ARE is lower bounded by $2\pi \approx 6.3$. This means that Fisher's LDA requires at least 6.3 more samples to achieve the same (asymptotic) power as the T^2 test. In this light, the accuracy test is remarkably inefficient. For comparison, the t-test is only 1.04 more (asymptotically) efficient than Wilcoxon's rank-sum test [44], so that an ARE of 6.3 is strong evidence in favor of the two-group test.

The analysis in [42] is asymptotic. Since typical sample sizes in neuroscience and genetics are not large, we seek to study which test is to be preferred in finite samples, and not only asymptotically. Lacking a unifying mathematical framework for the finite sample power analysis, we opt for a simulation study.

We start with formalizing the problem in Section II. The main findings are reported in Sections III, and IV. We conclude with a discussion.

II. PROBLEM SETUP

A. Multivariate Testing

Let $y \in \mathcal{Y}$ be a class encoding. Let $x \in \mathcal{X}$ be a p dimensional feature vector. In our vocal/non-vocal example we have $\mathcal{Y} = \{0, 1\}$ and $p = 27$, the number of voxels in a brain region so that $\mathcal{X} = \mathbb{R}^{27}$.

We denote a sample from x given y with x_y . We denote the distribution of x_1 by \mathcal{F} and x_0 with \mathcal{G} . Denoting a dataset by $\mathcal{S} := \{(x_i, y_i)\}_{i=1}^n$, a two-group test amounts to testing whether $\mathcal{F} = \mathcal{G}$. For example, we can test whether multivariate voxel activation patterns are similarly distributed when given a vocal stimulus (x_1) or a non-vocal one (x_0). The tests are calibrated to have a fixed false positive rate ($\alpha = 0.05$). The comparison metric between statistics is power, i.e., the probability to infer that $\mathcal{F} \neq \mathcal{G}$.

B. From a Test Statistic to a Permutation Test

The multivariate tests we will be considering rely on fixing some test statistic, \mathcal{T} , and comparing it to its permutation distribution. The tests differ in the statistic they employ. Our comparison metric is their power, i.e., their true positive rate. We adhere to permutation tests and not parametric inference because in our problems of interest central limit approximations are typically poor.

Because we focus on two-group testing under an independent sampling assumption, we know that a label-switching permutation test is valid. The sketch of our permutation test is the following:

- (a) Fix a test statistic \mathcal{T} with a right tailed rejection region.
- (b) Sample a random permutation of the class labels, $\pi(y)$.
- (c) Permute labels and recompute the statistic \mathcal{T}_π .
- (d) Repeat (a)-(c) R times.
- (e) The permutation p-value is the proportion of \mathcal{T}_π larger than the observed \mathcal{T} . Formally: $\mathbb{P}\{\mathcal{T}_\pi \geq \mathcal{T}\} := \frac{1}{R} \sum_{\pi} I\{\mathcal{T}_\pi \geq \mathcal{T}\}$.
- (f) Declare classes differ if the permutation p-value is smaller than α , which we set to $\alpha = 0.05$.

We now detail the various test statistics that will be compared.

C. Two-Group Tests

The most prevalent interpretation of “ x_1 is not distributed like x_0 ” is to assume they differ in means¹. Difference in means leads to the *shift class* of alternatives, which is by far the most studied class in the statistical literature. In his seminal work in 1931, Harold Hotelling proposed the T^2 test as a straightforward generalization of the t-test, for testing the equality in means of two multivariate distributions [45]. For more background see, for example, [46].

The major difficulty with the T^2 statistic is that it requires estimating a covariance matrix, thus introducing $p(p+1)/2 = \mathcal{O}(p^2)$ unknown parameters. If n is not much larger than p , or in low signal-to-noise (SNR), the test is very low powered, as shown in [25]. In these cases, high dimensional versions of the T^2 should be applied, which essentially regularize the estimator of Σ , thus reducing the dimensionality of the problem and improving the SNR and power. Examples of High-dim tests for dense shifts include [29], [25], [30], [31], [47], [48], [33], [49], [35], [50].

If $\mathbb{E}(x_1)$ differs from $\mathbb{E}(x_0)$ in a small number of coordinates we say the *signal is sparse*. To detect a sparse signal there is potentially no need to estimate all the coordinates of $\mathbb{E}(x_1) - \mathbb{E}(x_0)$, as done in the T^2 statistic, and its high-dim variants. Examples of high-dim tests statistics for sparse shifts include [51] and [28].

It is possible that the practitioner is unaware of the amount of sparsity in the signal. Some high-dim test statistics that *adapt* to the level of (unknown) sparsity include [52], [39], [40], [36], [41].

It is possible that the signal is present (not only) in means. We would thus opt for a two-group GOF test, instead of a location test. Examples of multivariate GOF tests include [53], [54], [14], [55], [56], [57], [2], [16], [15], [12].

¹This is not a logical equivalence, but rather a prevalent convention. The Behrnes-Fisher problem is a counter example where equal means do not imply equal distributions.

As previously mentioned, a classifier's accuracy may also be used as a test statistic. We now explain how this statistic is constructed.

D. Prediction Accuracy as a Test Statistic

An accuracy test amounts to using a predictor's accuracy as a test statistic. A predictor², $\mathcal{A}_S : \mathcal{X} \rightarrow \mathcal{Y}$, is the output of a learning algorithm \mathcal{A} when applied to the dataset S . The accuracy of predictor³, $\mathcal{E}_{\mathcal{A}_S}$, is defined as the probability of \mathcal{A}_S making a correct prediction. The accuracy of a learning algorithm⁴, $\mathcal{E}_{\mathcal{A}}$, is defined as the expected accuracy over all possible data sets S . Formalizing, we denote by \mathcal{P} the probability measure of (x, y) , and by \mathcal{P}_S the joint probability measure of the sample S . We can then write

$$\mathcal{E}_{\mathcal{A}_S} := \int_{(x,y)} \mathcal{I}\{\mathcal{A}_S(x) = y\} d\mathcal{P}, \quad (1)$$

and

$$\mathcal{E}_{\mathcal{A}} := \int_S \mathcal{E}_{\mathcal{A}_S} d\mathcal{P}_S, \quad (2)$$

where $\mathcal{I}\{A\}$ is the indicator function⁵ of the set A .

Denoting an estimate of $\mathcal{E}_{\mathcal{A}_S}$ by $\hat{\mathcal{E}}_{\mathcal{A}_S}$, and $\mathcal{E}_{\mathcal{A}}$ by $\hat{\mathcal{E}}_{\mathcal{A}}$, a statistically significant “better than chance” estimate of either, is evidence that the classes are distinct. Two popular estimates of $\hat{\mathcal{E}}_{\mathcal{A}}$ are the *resubstitution accuracy*⁶, and the V-fold Cross Validation (CV) estimate.

Definition 1 (Resubstitution accuracy). The resubstitution accuracy estimator of a learning algorithm \mathcal{A} , denoted $\hat{\mathcal{E}}_{\mathcal{A}}^{Resub}$, is defined as $\hat{\mathcal{E}}_{\mathcal{A}}^{Resub} := \frac{1}{n} \sum_{i=1}^n \mathcal{I}\{\mathcal{A}_S(x_i) = y_i\}$.

Definition 2 (V-fold CV accuracy). Denoting by \mathcal{S}^v the v 'th partition, or *fold*, of the dataset, and by $\mathcal{S}^{(v)}$ its complement, so that $\mathcal{S}^v \cup \mathcal{S}^{(v)} = \cup_{v=1}^V \mathcal{S}^v = \mathcal{S}$, the V-fold CV accuracy estimator, denoted $\hat{\mathcal{E}}_{\mathcal{A}}^{Vfold}$, is defined as $\hat{\mathcal{E}}_{\mathcal{A}}^{Vfold} := \frac{1}{V} \sum_{v=1}^V \frac{1}{|\mathcal{S}^v|} \sum_{i \in \mathcal{S}^v} \mathcal{I}\{\mathcal{A}_{\mathcal{S}^{(v)}}(x_i) = y_i\}$, where $|A|$ denotes the cardinality of a set A .

E. How to Estimate Accuracies?

Estimating $\hat{\mathcal{E}}_{\mathcal{A}}$ requires the following design choices: Should it be cross-validated and how? If cross validating using V-fold CV then how many folds? Should the folding be balanced? If estimation is part of a permutation test: should the data be refolded after each permutation?

We will now address these questions while bearing in mind that unlike the typical supervised learning setup, we are not interested in an unbiased estimate of $\mathcal{E}_{\mathcal{A}}$, but rather in the detection of its departure from chance level.

²Known as a *hypothesis* in the machine learning literature.

³Known as (the complement of) the *test error* in [58].

⁴Known as (the complement of) the *expected test error* in [58].

⁵Mutatis mutandis for continuous y .

⁶Known as (the complement of) the *train error* in [58].

a) *Cross validate or not*: For the purpose of statistical testing, bias in $\hat{\mathcal{E}}_{\mathcal{A}}$ is not a problem, as long as it does not invalidate the error rate guarantees. The underlying intuition is that if the same bias is introduced in all permutations, it will not affect the properties of the permutation test. We will thus be considering both cross validated accuracies, and resubstitution accuracies.

b) *Balanced folding*: The standard practice in V-fold CV is to constrain the data folds to be balanced, i.e. stratified [3, for e.g.]. This means that each fold has the same number of examples from each class. We will report results only with balanced folding, mostly because we will conclude that V-fold CV should not be used for our detection problem.

c) *Refolding*: In V-fold CV, *folding* the data means assigning each observation to one of the V data folds. The standard practice in neuroimaging is to permute labels and refold the data after each permutation. This is done because permuting labels will unbalance the original balanced folding. We will adhere to this practice due to its popularity, even though it is computationally more efficient to permute features⁷ instead of labels, as done by [59].

d) *How many folds*: Different authors suggest different rules for the number of folds. We fix the number of folds to $V = 4$, and do not discuss the effect of V because we will ultimately show that V-fold CV is dominated by other cross-validation procedures, and thus, never recommended.

Table I collects an initial battery of tests we will be comparing.

⁷The difference between permuting labels, $\pi(y)$, or features, $\pi(X)$, is in the mapping to folds. When permuting features, the *label* assignment to folds is fixed. When permuting labels, the *feature* assignment to folds is fixed.

Name	Algorithm	Resampling	Remark

TABLE I: This table collects the various test statistics we will be studying. Tests for dense shifts include: *Oracle*, *Hotelling*, *Schafer*, *Goeman*, and *Srivastava*. Tests for sparse shifts include *Cai*. Adaptive tests for shifts include *Simes*. The rests are accuracy tests with details given in the table. For example, *svm.CV.c100* is a linear SVM, with V-fold cross validated accuracy, and cost parameter set at 100 [60]. *svm.CV.cCV* is a linear SVM, with V-fold CV accuracy, and cost parameter optimized with (an inner) CV. *lda.noCV.1* is Fisher’s LDA, with a resubstituted accuracy estimate.

III. RESULTS

We now compare the power of our various statistics in various configurations. We do so via simulation. The basic simulation setup is presented in Section III-A. Following sections present variations on the basic setup. The R code for the simulations can be found in http://www.john-ros.com/permuting_accuracy/.

A. Basic Simulation Setup

Each simulation is based on 1,000 replications. In each replication, we generate n independent samples from a shift class

$$\mathbf{x}_i = \mu \mathbf{y}_i + \eta_i, \quad (3)$$

where $\mathbf{y}_i \in \mathcal{Y} = \{0, 1\}$ encodes the class of subject i , μ is a p -dimensional shift vector, the noise η_i is distributed as $\mathcal{N}_p(0, \Sigma)$, the sample size $n = 40$, and the dimension of the data is $p = 23$. The covariance $\Sigma = I$. In this basic setup, reported in Figure 1, the shift effect is captured by μ . Shifts are dense and equal in all p coordinates of μ . With e being a p -vector of ones, then $\mu := ce$. We will use c to index the signal’s strength, and vary it over $c \in \{0, 1/4, 1/2\}$. The (squared) Euclidean and Mahalanobis norms of the signal are $\|\mu\|_2^2 = \|\mu\|_\Sigma^2 = c^2 p \approx \{0, 1.4, 5.7\}$. These can be thought as the effect’s size.

Having generated the data, we compute each of the test statistics in Table I. For test statistics that require data folding, we used 4 folds. We then compute a permutation p-value by permuting the class labels, and recomputing

each test statistic. We perform 300 such permutations. We then reject the “ $x|y = 0$ distributed like $x|y = 1$ ” null hypothesis if the permutation p-value is smaller than 0.05. The reported power is the proportion of replication where the permutation p-value fell below 0.05.

B. False Positive Rate

We start with a sanity check. Theory suggests that all test statistics should control their false positive rate. Our simulations confirm this. In all our results, such as Figure 1, we encode the null case, where no signal is present and x_1 has the same distribution as x_0 , by a red circle. Since the red circles are always below the desired 0.05 error rate then the false positive rate of all test statistics, in all simulations is controlled. We may thus proceed and compare the power of each test statistic.

C. Power

From Figure 1 we learn that two-group tests are more powerful than accuracy tests.

Fig. 1: The power of the permutation test with various test statistics. The power on the x axis. Effects are color and shape coded. The various statistics on the y axis. Their details are given in Table I. Effects vary over $c = 0$ (red circle), $c = 1/4$ (green triangle), and $c = 1/2$ (blue square). Simulation details in Section III-A. Cross-validation was performed with balanced and unbalanced data folding; see sub-captions.

D. Large Sample

We focus on high-dim–small-sample configurations because of our motivation in neuroimaging and genetics. Our results, however, are qualitatively invariant to the small sample, and hold also in high-dim–large-sample configurations. To prove this point, we fix p/n at $23/40$, and set $n = 4,000, p = 2,300$. The results are reported in Figure 2.

Fig. 2: The same as Figure 1 with $n = 4,000; p = 2,300$.

E. Departure From Gaussianity

The Neyman-Pearson Lemma (NPL) type reasoning that favors two-group location-tests over accuracy tests, may fail when the data is not multivariate Gaussian, and Hotelling’s T^2 statistic no longer a generalized-likelihood-ratio test.

To check this, we replaced the multivariate Gaussian distribution of η in Eq.(3) with a heavy-tailed multivariate- t distribution. In this heavytailed setup, the dominance of the two-group tests was preserved, even if less evident than in the Gaussian case (Figure 3).

Fig. 3: **Heavytailed.** η_i is p -variate t , with $df = 3$.

F. Departure from Sphericity

We now test the robustness of our results to the correlations in x . In terms of Eq.(3), Σ will no longer be the identity matrix. Intuitively- almost all tests include some estimator of Σ , so that correlations should be accounted for. To keep the comparisons “fair” as the correlations vary, we kept $\|\mu\|_{\Sigma} := \sqrt{\mu' \Sigma^{-1} \mu}$ fixed.

Which test has more power: accuracy or two-group? We address this question using various correlation structures. We also vary the direction of the signal, μ , and distinguish between signal in high variance principal component (PC) of Σ , and in the low variance PC.

The simulation results reveal some non trivial phenomena. First, when the signal is in the direction of the high variance PC, the high dimensional two-group tests are far superior than accuracy tests. This holds true for various correlation structures: the short memory correlations of $AR(1)$ in Figure 4a, the long memory correlations of a Brownian motion in Figure 5a, and the arbitrary correlation in Figure 6a.

When the signal is in the direction of the low variance PC, a different phenomenon appears. There is no clear preference between two-group or accuracy tests. Instead the non-regularized tests are the clear victors. This holds true for various correlation structures: the short memory correlations of $AR(1)$ in Figure 4b, the long memory correlations of a Brownian motion in Figure 5b, and the arbitrary correlation in Figure 6b. We attribute this

phenomenon to the bias introduced by the regularization, which masks the signal. This matter is further discussed in Section V-C.

Fig. 4: Short memory, AR(1) correlation. $\Sigma_{k,l} = \rho^{|k-l|}$; $\rho = 0.6$

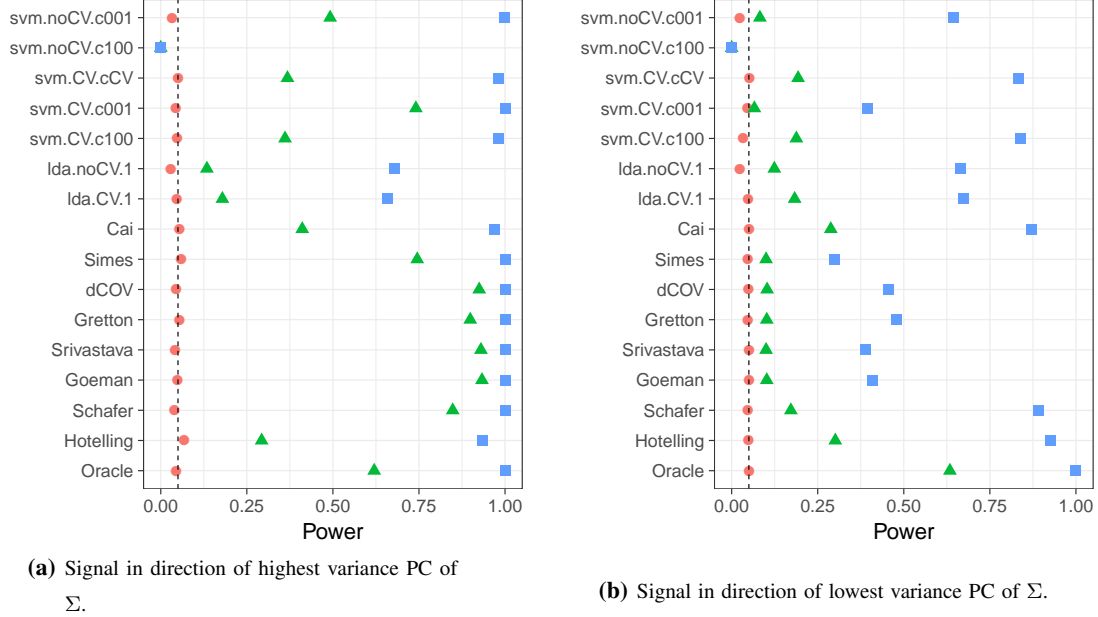

Fig. 5: Long-memory Brownian motion correlation: $\Sigma = D^{-1}RD^{-1}$ where D is diagonal with $D_{jj} = \sqrt{R_{jj}}$, and $R_{k,l} = \min\{k, l\}$.

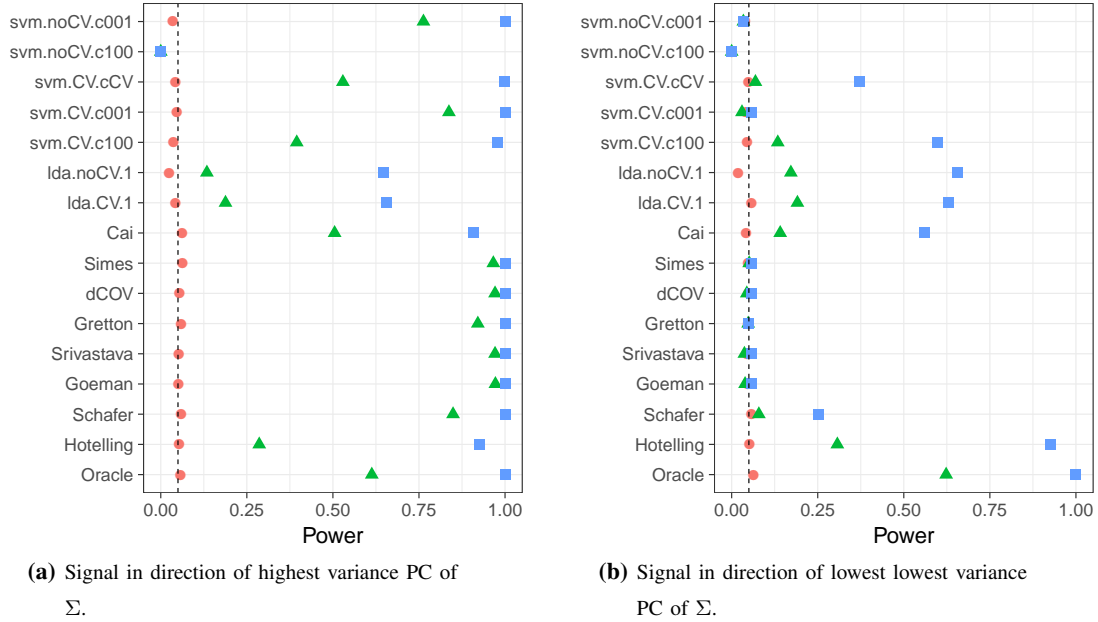

Fig. 6: Arbitrary Correlation. $\Sigma = D^{-1}RD^{-1}$ where D is diagonal with $D_{jj} = \sqrt{R_{jj}}$, and $R = A'A$ where A is a Gaussian $p \times p$ random matrix with independent $\mathcal{N}(0, 1)$ entries.

G. Departure from Homoskedasticity

Our previous simulations assume variables have unit variance. Some test statistics have built-in variance normalization, and are known as *scalar invariant*. Dealing with the heteroskedastic case, where different coordinates have different variance, is of lesser importance, since we can typically normalize the variable-wise variance. Indeed, practitioners are already accustomed to z-score features before learning a regularized predictor (e.g. ridge regression).

The *Srivastava* statistic, for instance, is scalar invariant. It can be (roughly) thought of as the l_2 norm of mean-difference vector. The *Goeman* statistic, for instance, is not scalar invariant. It can be (roughly) thought of as the l_2 norm of the vector of univariate t^2 statistics. The *Goeman* statistic will thus give less importance to signal in the high-variance directions than signal in the low-variance directions, whereas *Srivastava* will give all coordinates the same importance.

In Figure 7a we see that as before, two-group tests dominate accuracy tests. We can see the difference between the scalar-invariant *Srivastava* and *Goeman* statistics: the latter gains power by focusing on low variance coordinates. Since the signal's magnitude is the same in all coordinates, *Goeman* gains power by putting emphasis where it is most informative.

When the signal is in the low variance PC, *Goeman* puts emphasis on variables which carry little signal. For this reason it has less power than *sd*, as seen in Figure 7b.

Fig. 7: Heteroskedasticity: Σ is diagonal with $\Sigma_{jj} = j$.(a) μ in the high variance PC of Σ .(b) μ in the low variance PC of Σ .

H. Departure from V -fold CV

Intuition suggests we may alleviate the discretization of the accuracy test statistic by replacing the V -fold CV, and resampling *with replacement*. The discretization of the accuracy statistic is governed by the number of samples in the union of test sets. For V -fold CV, for instance, the accuracy may assume as many values as the sample size. This suggests that the accuracy can be “smoothed” by allowing the test sample to be drawn with replacement. An algorithm that samples test sets with replacement is the *leave-one-out bootstrap estimator*, and its derivatives, such as the *0.632 bootstrap*, and *0.632+ bootstrap* [58, Sec 7.11].

Definition 3 (bLOO). The *leave-one-out bootstrap* estimate, bLOO, is the average accuracy of the holdout observations, over all bootstrap samples. Denote by S^b , a bootstrap sample b of size n , sampled with replacement from \mathcal{S} . Also denote by $C^{(i)}$ the index set of bootstrap samples not containing observation i . The leave-one-out bootstrap estimate, $\hat{\mathcal{E}}_{\mathcal{A}}^{bLOO}$, is defined as:

$$\hat{\mathcal{E}}_{\mathcal{A}}^{bLOO} := \frac{1}{n} \sum_{i=1}^n \frac{1}{|C^{(i)}|} \sum_{b \in C^{(i)}} \mathcal{I}\{\mathcal{A}_{S^b}(x_i) = y_i\}. \quad (4)$$

An equivalent formulation, which stresses the Bootstrap nature of the algorithm is the following. Denoting by $S^{(b)}$ the indexes of observations that are *not* in the bootstrap sample b and are not empty,

$$\hat{\mathcal{E}}_{\mathcal{A}}^{bLOO} = \frac{1}{B} \sum_{b=1}^B \frac{1}{|S^{(b)}|} \sum_{i \in S^{(b)}} \mathcal{I}\{\mathcal{A}_{S^b}(x_i) = y_i\}. \quad (5)$$

Simulation results are reported in Figure 8 with naming conventions in Table II. As expected, selecting test sets with replacement does increase the power of accuracy tests, when compared to V -fold cross validation, but still

falls short from the power of two-group tests. It can also be seen that power increases with the number of bootstrap replications, since more replications reduce the level of discretization.

I. The Effect of High Dimension

Our setup of $n = 40$ and $p = 23$ is high-dim–small-sample, which surfaces finite-sample effects, not manifested in classical $p/n \rightarrow 0$ asymptotic analysis. Our best performing tests alleviate the dimensionality of the problem by

regularizing the estimation of Σ . Shrinking, or thresholding the entries of $\hat{\Sigma}$ reduces variance at the cost of some (possible) bias. The power advantages of the two-group tests may be driven by the regularization of the covariance, and not the statistic itself. To answer this question we augment the comparison with some accuracy tests that have explicit covariance regularization built in.

We now some covariance-regularized accuracy tests such as a shrinkage based LDA [61], [62], where similarly to *Schafer*, Tikhonov regularization of $\hat{\Sigma}$ is employed. We also try we try a diagonalized LDA⁸ [63], which regularizes $\hat{\Sigma}$ similarly to *sd* and *Goeman*.

Simulation results are reported in Figure 9 with naming conventions in Table III. The proper regularization of the covariance of a classifier, just like a two-group test, can improve power. See, for instance, *svm.CV.c001* which is clearly the best regularized SVM for testing. Replacing the V-fold with a bootstrap allows us to further increase the power, as done with *lda.highdim.Pang.b50*. Even so, the out-of-the-box two-group tests outperform the accuracy tests.

It is interesting to note that *svm.CV.cCV* is not a good performer. In SVMs, the cost parameter governs the magnitude of the margins, and thus the regularization. In *svm.CV.cCV* this regularization is optimized with CV which leads us to argue that the optimal cost for predicting is not the same as the optimal cost for testing.

Name	Algorithm	Resampling	Parameters
lda.highdim.Dudoit.CV	[63]	V-fold	–
lda.highdim.Ramey.CV	[62]	V-fold	–
lda.highdim.Pang.CV	[61]	V-fold	–
lda.highdim.Pang.b50	[61]	bLOO	B=50

TABLE III: The same as Table I for regularized (high dimensional) predictors.

IV. NEUROIMAGING EXAMPLE

Figure 10 is an application of both a two-group and an accuracy test to the neuroimaging data of [64]. The authors of [64] collected fMRI data while subjects were exposed to the sounds of human speech (vocal), and other non-vocal sounds. Each subject was exposed to 20 sounds of each type, totaling in $n = 40$ trials. The study was rather large and consisted of about 200 subjects. The data was kindly made available by the authors at the OpenNeuro website⁹.

We perform group inference using within-subject permutations along the analysis pipeline of [65], which was also reported in [24]. To demonstrate our point, we compare the *Srivastava* two-group test with the linear SVM accuracy test.

In agreement with our simulation results, the two-group test (*Srivastava*) discovers more brain regions of interest when compared to an accuracy test. The former discovers 1,232 regions, while the latter only 441, as depicted in Figure 10. We emphasize that both test statistics were compared with the same permutation scheme, and the same error controls, so that any difference in detections is due to their different power.

⁸Known as *Gaussian Naïve Bayes*.

Fig. 9: **HighDim Classifier**. The power of a permutation test with various test statistics. The power on the x axis. Effects are color and shape coded. The various statistics on the y axis. Their details are given in tables I and III. Effects vary over 0 (red circle), 0.25 (green triangle), and 0.5 (blue square). Simulation details in Section III-A.

V. DISCUSSION

We have set out to understand which of the tests is more powerful: accuracy tests or two-group tests. Our current observation is that accuracy tests are never optimal; there is always a two-group test that dominates in power. Our advice to the practitioner is that two-group tests, in particular their high-dim versions, are good performers in a wide range of simulation setups. They are also typically easier to implement, and faster to run, since no resampling is required. Statistics such as *Schafer*[30], *Goeman*[31], *Srivastava*[32], *dCOV*[55], and *Gretton*[12], are particularly well suited for the dense signal expected in neuroimaging.

A. Where do Accuracy Tests Lose Power?

The low power of the accuracy tests compared to two-group tests can be attributed to the following causes.

1) *Data Splitting*: Cross-validated statistics split the data. The train set serves to learn a statistic, and the test set to compute it. In a train-test validation scheme, the effective sample size is that of the test set. This is clearly inefficient. In V-fold validation scheme, the statistic is the average over all test sets, so the effective sample size is

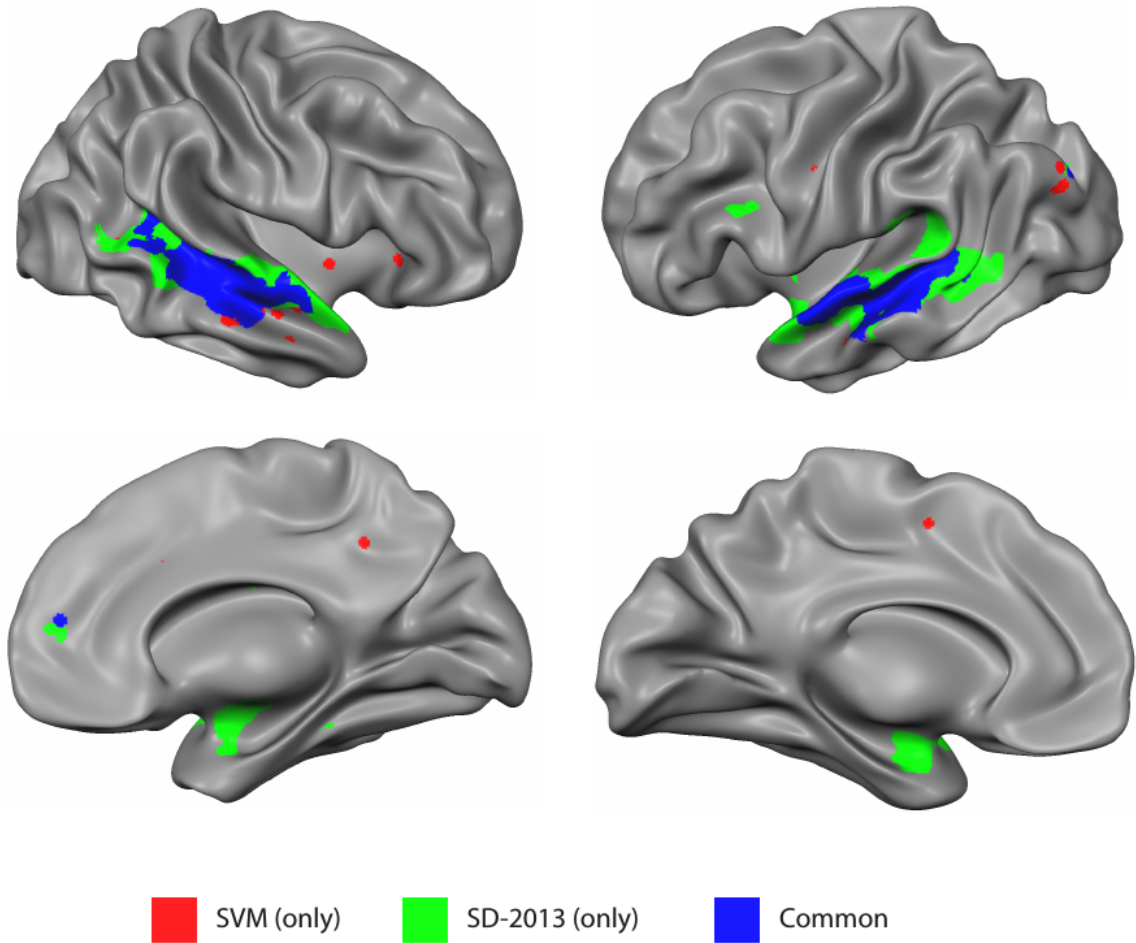

Fig. 10: Brain regions encoding information discriminating between vocal and non-vocal stimuli. Map reports the centers of 27-voxel sized spherical regions, as discovered by an accuracy test u and a two-group test (*Srivastava*). The linear SVM was computed using 5-fold cross validation, and a cost parameter of 1. Region-wise significance was determined using the permutation scheme of [65], followed by region-wise $FDR \leq 0.05$ control using the Benjamini-Hochberg procedure [66]. Number of permutations equals 400. The two-group test detect 1,232 regions, and the accuracy test 441, 399 of which are common to both. For the details of the analysis see [24].

less obvious. We still argue that this is an inefficient use of the data, as seen in the distributed learning literature, where splitting the sample and averaging is less accurate than learning with the whole data [67].

The superiority of the Bootstrap over V-fold was independently observed in [11]. According to these authors, this superiority is due to the larger test-samples when Bootstrapping, compared to V-folding.

2) *Inappropriate Regularization:* The fact that $svm.CV.cCV$ is less accurate than $svm.CV.c001$ we learn than testing requires different regularization than predicting. Does testing require more or less regularization? [TODO: compare costs of cv svm to fixed cost] Intuitively, when the signal is in the location μ , then predicting requires a regularizing bias in the order of $\|\mu\|_2$, while testing requires a bias in the order of $\|\mu\|_\infty$. The gap may be

considerable in high-dimension. This phenomenon was also observed by [68], which observe that recovering the support of a function requires less regularization than recovering the whole function.

3) *Discretization*: [TODO: explain that LDA is Hotelling+discretization] Permutation testing with discrete test statistics are known to be conservative. Firstly, because a Monte-Carlo sample of permutations will always be conservative compared to a full enumeration of permutations [69]. Secondly, because of the presence of ties which does not allow to exhaust the permissible false positive rate, unless randomization is introduced. Thirdly, because a highly discrete test-statistic, is insensitive to mild perturbations of the data. For an intuition consider the usage of the *resubstitution accuracy*, a.k.a. the *train error*, or *empirical risk*, as a test statistic. Resubstitution accuracy is the accuracy of the classifier evaluated on the training set. If data is high dimensional, the resubstitution accuracy will be very high due to over fitting. In a very high dimensional regime, the resubstitution accuracy may be as high as 1 for the observed data [70, Theorem 1], but also for any permutation. The concentration of resubstitution accuracy near 1, and its discretization, render this test completely useless, with power tending to 0 for any (fixed) effect size, as the dimension of the model grows. This explains the terrible power of *svm.noCV.c100*.

The degree of discretization is governed by the sample size. For this reason, an asymptotic analysis such as [42], or [59], will not capture power loss due to discretization¹⁰. An asymptotic analysis may suggest resubstitution accuracy estimates are good test statistics, while they suffer from very low finite-sample power. The canonical remedy for ties— random tie breaking — showed only a minor improvement (Sec. ??).

Using our simulations we may quantify the power loss due to discretization. This is because Figher’s LDA is essentially ordinary least squares with a discretization stage. [TODO: add figure with OLS classifier]

The matter of discretization can be summarized by a 2011 post by Prof. Frank Harrell in *CrossValidated*¹¹:

... your use of proportion classified correctly as your accuracy score. This is a discontinuous improper scoring rule that can be easily manipulated because it is arbitrary and insensitive.

B. Interpretation

Two-group tests, and location tests in particular, are easier to interpret. To do so we typically use a NPL type argument, and think: What type of signal is a test sensitive to? What is the direction of the effect? etc. Accuracy tests are seen as “black boxes”, even though they can be analyzed in the same way. [71] demonstrate that the type of signal captured by accuracy tests is less interpretable to neuroimaging practitioners than two-group tests.

Some authors prefer accuracy tests because they can be seen as effect-size estimates, invariant to the sample size. This is true, but the multivariate-statistics literature provides many multivariate effect-size estimators, that generalize Cohen’s d. Examples can be found, for instance, in [72] and references therein.

¹⁰This actually holds for all power analyses relying on a *contiguity* argument [43, Ch.6].

¹¹A Q&A website for statistical questions: <http://stats.stackexchange.com/questions/17408/how-to-assess-statistical-significance-of-the-accuracy-of-a-classifier>. And also “Problems with Classification of Predictions” in his book: <http://www.fharrell.com/doc/bbr.pdf>

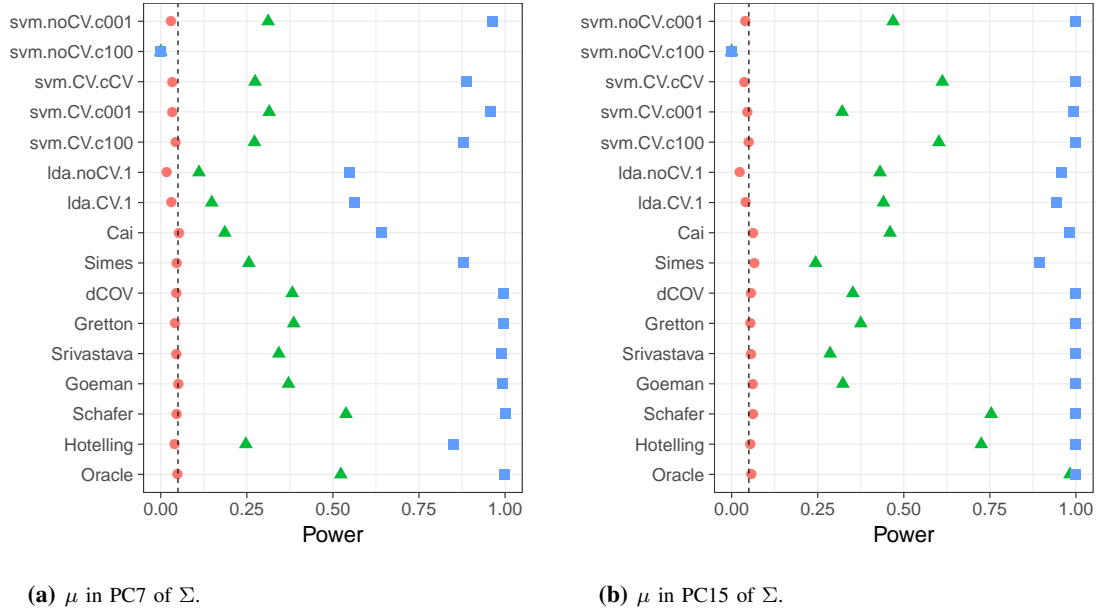

C. Fixed SNR

For a fair comparison between simulations, in particular between those with different Σ , we needed to fix the difficulty of the problem. For “a fair comparison” we fix the Kullback–Leibler Divergence between distributions of sample means. Abusing notation, we fix $KL[\bar{x}_1, \bar{x}_0] = c^2 p$.

Our choice implies that the Euclidean norm of $\delta := \mathbb{E}(x_1) - \mathbb{E}(x_0)$ varies with Σ , with the sample size, and with the direction of the signal. An initial intuition may suggest that detecting signal in the low variance PCs is easier than in the high variance PCs. This is true when fixing $\|\mu\|_2$, but not when fixing $KL[\bar{x}_1, \bar{x}_0]$.

For completeness, Figure 11 reports the power analysis under $AR(1)$ correlations, but with $\|\mu\|_2$ fixed. We compare the power of a shift in the direction of some high variance PC (Figure 11a), versus a shift in the direction of a low variance PC (Figure 11b). The intuition that it is easier to detect signal in the low variance directions is confirmed.

Fig. 11: Short memory, $AR(1)$ correlation. $\|\mu\|_2$ fixed.

Other authors have also observed the need for fixing the SNR for a fair comparison between tests. In [73], authors prefer to use sparse alternatives. With sparse alternatives, the difficulty of the problem is governed by the sparsity of the signal and not only the dimension of the data. In [74], authors fix $\|\mu\|^2 / \|\Sigma\|_{Frob}$ where $\|\Sigma\|_{Frob} = \sqrt{\text{Tr}(\Sigma' \Sigma)}$ is the Frobenius matrix norm. Clearly, $\|\mu\|^2 / \|\Sigma\|_{Frob}$ is invariant to the direction of the signal with respect to the noise. For this reason, we prefer our own approach.

D. Detecting Signal in Different Directions

Figures 4, 5, 6 and 11, demonstrate that detecting signal in the direction of the high variance PCs is very different than detecting in the low variance PCs. Why is that?

We attribute this phenomenon to regularization. While the signal, μ varies in direction, the regularization of $\hat{\Sigma}$ does not. We borrow intuition from ridge regression where closed form solutions are available. We first recall that in ridge regression

$$\hat{y} = X'(\hat{\Sigma} + \lambda I)^{-1} X' y,$$

so that penalizing $\|\beta\|_2^2$, ends up regularizing the covariance estimator. Using the SVD decomposition of the design, then

$$\hat{y} = \sum_{j=1}^p \left(u_j \frac{d_j^2}{d_j^2 + \lambda} u_j' \right) y, \quad (6)$$

where $X = (u_1, \dots, u_p) \text{diag}(d_1, \dots, d_p) (v_1', \dots, v_p')$. From Eq.(6) we see that the bias is larger in the directions of the smaller d_j , i.e., the smaller noise components.

This intuition explains figures 4b, 5b, and 6b: the fact that unregularized tests have more power than the regularized.

E. Sparse Alternatives

In our set of simulations we discussed “dense” alternatives, in the sense that all coordinates carry signal. Dense alternatives are motivated by neuroimaging where most brain locations in a regions carry signal. In a genetic application, a “sparse” alternative may be more plausible. Figure ?? reports the usual results, where μ is sparse. As usual, two-group tests dominate accuracy tests, only this time, the winners are not the T^2 type statistics, but rather, the tests for sparse shifts (*Cai, Simes*).

F. Implications to Other Problems

Our work studies signal detection in the two-group multivariate testing framework, i.e., MANOVA framework. The same problem can be cast in the univariate generalized linear models framework, and in particular, as a Brenoulli Regression problem. If any of the predictors, x , carries any signal, then x_0 has a different distribution than x_1 . This view is the one adopted [31].

Another related problem is that of multinomial-regression, i.e., multi-class classification. We conjecture that power differences in favor of two-group tests versus accuracy tests will increase as the number of classes increases.

G. Feature Mapping

It may be argued that only accuracy tests permits the separation between classes in augmented spaces, such as in *reproducing kernel Hilbert spaces* (RKHS) by using non-linear predictors. This is a false argument— accuracy tests do not have any more flexibility than two-group tests. One can always perform a two-group test after mapping the original features to some augmented space. This is the case, for instance, of the *Gretton* statistic [12].

A slightly different argument is that the feature mapping may not be known, but rather learned from the data. We find this to be a weak argument. First, tests may also learn feature mappings that maximize power. This is explicit in the construction of the *Gretton* statistic [12], and also in [15]. Secondly, and perhaps more importantly

Fig. 12: Sparse μ .

to our setup, in high-dim problem is data is barely sufficient to learn covariances in the original space. We thus have little hope of learning covariances in augmented spaces. This is perhaps the reason why [75], who proposed using the covariance of the feature maps in RKHS, demonstrated their solution using a known covariance, and did not try to estimate it from data.

H. A Good Accuracy Test

Brain-computer interfaces and clinical diagnostics [76], [77] are examples in which we want to know not only if information is encoded in a region, but rather, that a particular predictor can extract it. In these cases an accuracy test cannot be replaced by a two-group test. For the cases an accuracy test cannot be replaced with other tests, we collect the following observations.

a) *Sample size*: The conservativeness of accuracy tests, due to discretization, decrease with the size of the test set.

b) *Regularize*: Regularization proves crucial to detection power in low SNR regimes, such as when n is in the order of p , or under strong correlations. We find that the Shrinkage-based Diagonal Linear Discriminant Analysis of [61] is a particularly good performer, but more research is required on this matter.

c) *Smooth accuracy*: Smooth accuracy estimate by cross validating with replacement. The bLOO estimator, in particular, is preferable over V-fold. This was also observed by [11], albeit attributed to the stability of the accuracy estimate, and not to its smoothness.

d) *Resubstitution accuracy in high SNR*: Resubstitution accuracy is useful in high SNR regimes, such as $n \gg p$, because it avoids cross validation without compromising power. In low SNR, the power loss is considerable. We attribute this to the compounding of discretization and concentration effects: the difference between the sampling distribution of the resubstitution accuracy is simply indistinguishable under the null and under the alternative.

I. Mixture Classes

[18] and [59] study accuracy tests using simulation, neuroimaging data, genetic data, and analytically. The finite Vapnik–Chervonenkis dimension requirement [59, Sec 4.3] implies a the problem is low dimensional and prevents the permutation p-value from (asymptotically) concentrating near 1. They find that the power increases with the size of the test set. This is seen in Fig.4 of [59], where the size of the test-set, K , governs the discretization. We attribute this to the reduced discretization of the accuracy statistic.

[59] simulate the power of accuracy tests by sampling from a Gaussian mixture family of models, and not from a location family as our own simulations. Under their model (with some abuse of notation)

$$\begin{aligned}(x_i|y_i = 1) &\sim \pi\mathcal{N}(\mu_1, I) + (1 - \pi)\mathcal{N}(\mu_2, I), \\ (x_i|y_i = 0) &\sim (1 - \pi)\mathcal{N}(\mu_1, I) + \pi\mathcal{N}(\mu_2, I).\end{aligned}$$

Varying π interpolates between the null distribution ($\pi = 0.5$) and a location shift model ($\pi = 0$). We now perform the same simulation as [59], and in the same dimensionality as our previous simulations. We re-parameterize so that $\pi = 0$ corresponds to the null model:

$$\begin{aligned}(x_i|y_i = 1) &\sim (1/2 - \pi)\mathcal{N}(\mu_1, I) + (1/2 + \pi)\mathcal{N}(\mu_2, I), \\ (x_i|y_i = 0) &\sim (1/2 + \pi)\mathcal{N}(\mu_1, I) + (1/2 - \pi)\mathcal{N}(\mu_2, I).\end{aligned}\tag{7}$$

From Figure 13, we see that also for the mixture class of [59] locations tests are to be preferred over accuracy tests.

J. Epilogue

Given all the above, we find the popularity of accuracy tests for signal detection quite puzzling. We believe this is due to a reversal of the inference cascade. Researchers first fit a classifier, and then ask if the classes are any different. Were they to start by asking if classes are any different, and only then try to classify, then two-group tests would naturally arise as the preferred method. As put by [42]:

The recent popularity of machine learning has resulted in the extensive teaching and use of prediction in theoretical and applied communities and the relative lack of awareness or popularity of the topic of Neyman-Pearson style hypothesis testing in the computer science and related “data science” communities.

Fig. 13: **Mixture Alternatives.** \mathbf{x}_i is distributed as in Eq.(7). μ is a p -vector with $3/\sqrt{p}$ in all coordinates. The effect, π , is color and shape coded and varies over 0 (red circle), $1/4$ (green triangle) and $1/2$ (blue square).
