

Better-than-chance classification for signal detection

Jonathan Rosenblatt Roei Gilron Roy Mukamel

July 28, 2016

Abstract

[TODO]

1 Introduction

A common workflow in genetics or neuroimaging consists of fitting a classifier, and estimating its predictive accuracy using cross validation. Given that the cross validated accuracy is a random quantity, it is then common to test if the cross validated accuracy is significantly better than chance using a permutation test. Genetic examples include Jiang et al. [2008], Radmacher et al. [2002] [TODO: elaborate]. Neuroscience examples include the very popular *multivariate pattern analysis* (MVPA) [Kriegeskorte et al., 2006, Varoquaux et al., 2016, Golland and Fischl, 2003]. The number of citations¹ attests to the popularity of the above workflow: =956 for Kriegeskorte et al. [2006], and 274 for Radmacher et al. [2002], as examples.

To fix ideas, we will adhere to a Neuroscientific example: In Gilron et al. [2016], the authors seek to detect auditory brain regions which distinguish between vocal and non-vocal stimuli. According to the MVPA analysis workflow, the localization problem is cast as a supervised learning problem: if the type of the stimulus can be predicted from the spatial activation pattern, significantly better than chance, then a region is declared to encode vocal/non-vocal information. We call this an *accuracy test*.

This same signal detection task can be also approached as a two-group multivariate test: Inferring that a region encodes vocal/non-vocal information, is essentially inferring that the spatial distribution of brain activations is different given a vocal/non-vocal stimulus. A practitioner may then call

¹Based on GoogleScholar. Accesses on 26.7.2016.

25 upon a two-group location test such as Hotelling’s T^2 Fujikoshi et al. [2011].
 26 Alternatively, if the size of the brain region is too large compared to the num-
 27 ber of observations, so that the spatial covariance cannot be fully estimated,
 28 then a high dimensional version of Hotelling’s test can be called upon, such
 29 as in Srivastava [2013] or Schäfer et al. [2005]. In contrast to *accuracy tests*,
 30 we call these *location tests*.

31 At this point, it becomes unclear which is the preferred test. This was
 32 precisely the topic of Ramdas et al. [2016], who compared the Hotelling
 33 location test to the accuracy of *Fisher’s linear discriminant analysis* classifier
 34 (LDA) [Hastie et al., 2003]. Using an asymptotic analysis, Ramdas et al.
 35 [2016] concluded that accuracy and location tests are equivalent with respect
 36 to their order of convergence to a consistent test, while they may differ in
 37 constants.

38 Those constants, governing the power of the tests, are crucial when deal-
 39 ing with typical sample sizes in neuroscience and genetics, and thus the focus
 40 of this study. In particular, which test is to be preferred in finite samples?
 41 Our conclusion is quite simple: *location tests almost always have more power*
 42 *than accuracy tests*.

43 The main argument for our statement rests upon the observation that
 44 with typical sample sizes, the accuracy test statistic is highly discrete. Dis-
 45 crete test statistics are known to be conservative [Hemerik and Goeman,
 46 2014], since they cannot exhaust the permissible false positive rate. In accu-
 47 racy tests, the degree of discretization of the accuracy statistic is governed
 48 by the number of samples. In our running neuroscience example [Gilron
 49 et al., 2016], the classification is performed based on 40 trials, so that the
 50 test statistic may assume only 40 possible values. This number of examples
 51 is not unusual if considering this is the number of subject in a genetic study,
 52 or the number of trial repeats in an fMRI brain scan.

53 The discretization effect is aggravated if the test statistic is highly concen-
 54 trated. For an intuition consider the usage of the train-accuracy test statistic
 55 (i.e., not cross validated). Because the testing problem is high dimensional,
 56 the observed train accuracy will be close to 1. The same will occur in every
 57 permutation, for the same reason. The permutation p-value will thus be 1
 58 for almost all data sets, the null will never be rejected, and the test will have
 59 no power.

60 Given these considerations, it is quite surprising that signal detection
 61 using accuracy tests is so popular in neuroscience and genetics. In the fol-
 62 lowing, we quantify the power loss to be expected in typical studies, and
 63 identify the problems’ characteristics that govern its severity. We start by
 64 establishing a best practice for permutation testing using the accuracy test
 65 statistic, We also discuss the problem characteristics that govern the mag-

66 nitude of the conservativeness, and try to offer an intuition to the scope of
 67 the observation that a multivariate test should always be preferred over a
 68 classification approach.

69 2 Problem setup

70 Adhering to our neuroscientific example, we now formalize terminology and
 71 notation. Let $y \in \mathcal{Y}$ be a class encoding. In our vocal/non-vocal example,
 72 using effect coding, we have $\mathcal{Y} = \{-1, 1\}$. Let $x \in \mathcal{X}$ be a p dimensional
 73 feature vector. In our vocal/non-vocal example p is governed by the number
 74 of voxels in a regions, which is the number of voxels in each brain region
 75 tested. We thus have $\mathcal{X} = \mathbb{R}^{27}$.

76 Given n pairs of (x_i, y_i) , typically assumed i.i.d., the *testing* approach to
 77 localization amounts to testing whether $x|y = 1$ has the the same distribution
 78 as $x|y = -1$. I.e., the multivariate voxel activation pattern has the same
 79 distribution when given a vocal stimulus, as when given a non-vocal stimulus.
 80 The *classification* approach to the localization problem amounts to learning a
 81 predictive model $\hat{f}(x)$ from some assumed model class $\hat{f} \in \mathcal{F}$. The prediction
 82 accuracy, denoted $T_{\hat{f}}^{acc}$, is defined as the probability of a given classifier \hat{f}
 83 of making a correct prediction $T_{\hat{f}}^{acc} := P(\hat{f}(x) = y)$ when given a new,
 84 randomly drawn data point, (x, y) .

85 2.1 Candidate Tests

86 The design of a permutation test using the prediction accuracy, requires the
 87 following design choices:

88 **What test statistic?**

89 **Cross validated or not?** Is the statistic cross validated or not?

90 **Refolding?** For a K-fold cross validated test statistic: is the data refolded
 91 in each permutation?

92 **Permute labels of features?** Should the y be permuted or should the x ?

93 **Balanced folding?** For a K-fold cross validated test statistic: is the data
 94 folding balanced? (a.k.a. stratified).

95 **How many folds?** We will now address these questions while bearing in
 96 mind that unlike the typical supervised learning setup, we are not in-
 97 terested in an unbiased estimate of the prediction error, but rather in

the mere detection of a difference between two groups, leading to a better-than-chance accuracy.

What test statistic? Given a predictor \hat{f} , a natural test statistic is some estimate of its accuracy $T_{\hat{f}}^{acc}$. Then again, very low accuracies, even 0, is evidence that the classes are separated, and we only need to invert the predictions. We can thus consider some estimate of $|T_{\hat{f}}^{acc} - 0.5|$ as the test statistic. This, however, implies that if the classes are identical, random guessing has a 0.5 accuracy. This is not true if the classes are not balanced. The chance level in which case is the prevalence of the dominant class, we denote by \hat{p}_{max} . This suggests the following test statistic $|T_{\hat{f}}^{acc} - \hat{p}_{max}|$. Since we will later be aggregating these statistic over random data foldings, where the dominant class may have varying frequencies, it seems appropriate to standardize the scale of this statistic. We thus also consider a z-scored accuracy: $|T_{\hat{f}}^{acc} - \hat{p}_{max}| / \sqrt{\hat{p}_{max}(1 - \hat{p}_{max})}$.

Cross validated or not? Were we interested in an unbiased estimator of the prediction error, there is no question that some validation is in order. Since we are merely interested in detecting a difference between groups, a biased error estimate is not an issue provided that it is consistent over all permutations. The underlying intuition is that if the exact same computation is performed over all permutations, then a permutation test will be “fair”, i.e., will not inflate the false positive rate. We will thus be considering both cross validated accuracies, and train accuracies as our test statistics.

Refolding? The standard practice in neuroimaging is to refold the data after each permutation. This is imperative if permuting labels while aiming at balanced data folds. This is not, however, imperative in general. In this work, we will adhere to the standard practice of refolding the data within each permutation.

Permute labels of features? While seemingly identical, the compounding of permutations with data foldings renders these two approaches distinct. As an example, consider balanced (stratified) K-fold cross validation where the initial data folding is balanced. After a label permutation, the folds will probably not be balanced, and will thus

have to be refolded. If the features are permuted, then the labels conserve their original fold assignments, and the data need not be refolded. Since we only report results while refolding the data in each permutation, then the only difference between permuting labels and permuting features seems to be a computational one. We thus adhere to the more common, albeit less efficient practice, of permuting labels.

Balanced folding? A standard practice when cross validating is to constrain the data folds to be balanced (i.e. stratified). This is well justified when aiming at unbiased accuracy estimation. This also simplifies matter when aiming at signal detection, as can be seen from the above discussion of the appropriate test statistic. Then again, it may complicate matters, as can be seen from the above discussion on label versus feature permutation. In general, it is not imperative in general, and we will indeed be comparing the effect of balanced foldings versus unbalanced. We will thus report results with both balanced and unbalanced data foldings.

How many folds? Different authors suggest different rules for the number of folds. We will be varying the number of folds, since it will affect the concentration of the estimated accuracy, which will have a crucial effect on the conservativeness of the permutation test. Our intuition suggests that since more folds imply a less concentrated estimate, then leave-one-out should be the less conservative, and 2-fold should be the most conservative.

By now, the reader will have observed that there are indeed many ways to perform a permutation test using a cross validated statistic. The subset of tests we will be comparing is collected for convenience in Table 1.

3 Controlling the False Positive Rate

In the first of our battery of simulations we verify that various test statistics and permutation schemes control the type I error. Figure ?? demonstrates that this is indeed the case. All our candidate tests control the type I error, with varying degrees of conservativeness. In particular: (a) if the folds are balanced or not, (b) if the labels are permuted or the features, (c) if the test statistic is varied, (d) if the regularization level of the support vector machine classifier (SVM) is varied, (e) if the number of folds is varied.

Name	Basis	CV	Accuracy	Parameters
Hotelling	Hotelling	–	–	shrink=FALSE
Hotelling.shrink	Hotelling	–	–	shrink=TRUE
lda.CV.1	LDA	TRUE	accuracy	–
lda.CV.2	LDA	TRUE	z-accuracy	–
lda.noCV.1	LDA	FALSE	accuracy	–
lda.noCV.2	LDA	FALSE	z-accuracy	–
sd	SD	–	–	–
svm.CV.1	SVM	TRUE	accuracy	cost=1e1
svm.CV.2	SVM	TRUE	accuracy	cost=1e-1
svm.CV.3	SVM	TRUE	z-accuracy	cost=1e1
svm.CV.4	SVM	TRUE	z-accuracy	cost=1e-1
svm.noCV.1	SVM	FALSE	accuracy	cost=1e1
svm.noCV.2	SVM	FALSE	accuracy	cost=1e-1
svm.noCV.3	SVM	FALSE	z-accuracy	cost=1e1
svm.noCV.4	SVM	FALSE	z-accuracy	cost=1e-1

Table 1: This table enumerates the various test statistics we will be studying. Three are location tests: Hotelling, Hotelling.shrink, and sd. *Hotelling* is the classical two-group T^2 statistic. *Hotelling.shrink* is a high dimensional version with the regularized covariance in Schäfer et al. [2005]. *sd* is another high dimensional version of the T^2 , from Srivastava et al. [2013]. The rest of the tests are variations of the linear SVM, and Fisher’s LDA, with varying accuracy measures, cross validated or not, and varying tuning parameters. For example, *svm.CV.4* is a linear SVM, with *libsvm*’s cost parameter set at 0.1, using the cross validated z-scored accuracy ($|T_{\hat{f}}^{acc} - \hat{p}_{max}|/\sqrt{\hat{p}_{max}(1 - \hat{p}_{max})}$, see Section 2.1). Another example is *lda.noCV.1*, which is Fisher’s LDA, returning the train accuracy, without cross validation, and without z-scoring.

4 Power

Having established that all of the tests in our battery control the false positive rate, it remains to be seen if they have similar power— at least when comparing the power of the various classifiers and multivariate tests. The results of Ramdas et al. [2016] suggest that power should be of the same order. On the other hand, the results of our previous sections suggest that the conservativeness of some of the considered tests can be considerable, rendering them underpowered.

[TODO: discuss power of various tests]

We see by now that the use of accuracy tests for signal detection is underpowered compared to location tests. The above simulations can hardly support such a universal statement. We will thus verify on a neuroimaging dataset, and discuss the causes for this phenomenon thus the scope of the

Figure 1: The power of a permutation test with various test statistics. The power on the x axis. Effect are color and shape coded. They are assumed to be equal in all the 23 dimensions, and vary over 0 (red circle), 0.25 (green triangle), and 0.5 (blue square). The various statistics on the y axis. Their details are given in Table 1. Simulation code available at [TODO].

179 statement.

180 5 Neuroimaging Example

181 Figure 2 is an application of our battery of tests to the data of Pernet et al.
 182 [2015]. The authors of Pernet et al. [2015] collected fMRI data while subjects
 183 were exposed to the sounds of human speech (vocal), and other non-vocal
 184 sounds. Each subject was exposed to 20 sounds of each type, totalling in
 185 $n = 40$ trials in each scan. The study was rather large and consisted of
 186 about 200 subjects. The data was kindly made available by the authors at
 187 the OpenfMRI website².

188 To verify the observation that location tests have more power than ac-
 189 curacy tests, we perform permutation inference using the pipeline of Stelzer
 190 et al. [2013], which was also used in Gilron et al. [2016]. For completeness,
 191 the pipeline is described in Appendix A. To demonstrate our point, we com-
 192 pare the *sd* location test with the *svm.cv.1* accuracy test (see Table 1 for the
 193 definition of these statistics).

²<https://openfmri.org/>

194 In agreement with our simulation results, the location test (*sd*) discovers
 195 more brain regions that encode information discriminating between vocal and
 196 non-vocal stimuli when compared to an accuracy test (*svm.cv.1*). The former
 197 discovers 1,232 regions, while the latter only 441, as reported in Figure 2. We
 198 emphasize that both test statistics were compared with the same permutation
 199 scheme, and the same error controls, so that any difference in detections is
 200 due to their different power.

201 Having established that accuracy tests are underpowered both in simula-
 202 tion and in application, we wish to identify the conditions under which this
 203 will occur, and discuss implications on the practice of accuracy tests.

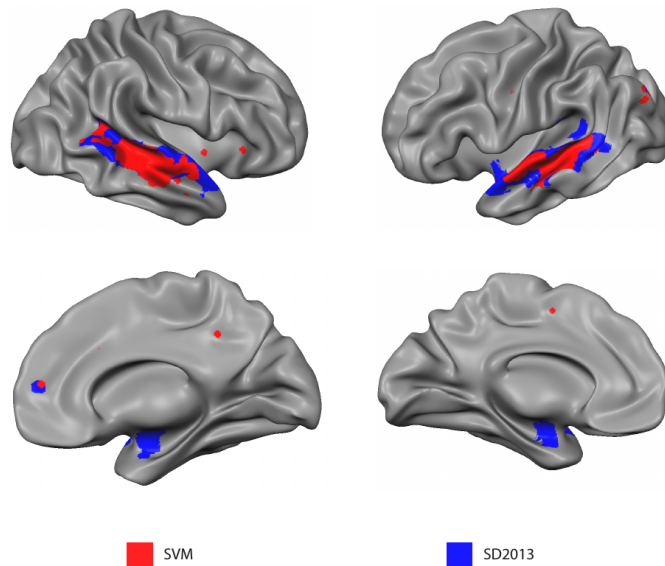

Figure 2: Brain regions encoding information discriminating between vocal and non-vocal stimuli. Map reports the centres of 27-voxel sized spherical regions, as discovered by an accuracy test (*svm.cv.1*), and a location test (*sd*). *svm.cv.1* was computed using 5-fold cross validation, and a cost parameter of 1. Region-wise significance was determined using the permutation scheme of Stelzer et al. [2013], followed by region-wise $FDR \leq 0.05$ control using the Benjamini-Hochberg procedure [Benjamini and Hochberg, 1995]. Number of permutations equals 400. The location test detect 1,232 regions, and the accuracy test 441. The overlap is such that 90% of the accuracy test regions, are also detected by the location test. For the details of the analysis see Appendix A and Gilron et al. [2016].

204 6 Discussion

205 We have set out to understand which of the tests is more powerful: the
 206 accuracy test or the location test. Using simulations, we have concluded

207 that the location tests are preferable. We attribute this to the discretization
 208 introduced in finite samples by the accuracy test statistic. This also explains
 209 why an asymptotic analysis, such as Ramdas et al. [2016], did not find a
 210 qualitative difference.

211 At this point some reservations to the generality of our findings are in
 212 order. Firstly, not all accuracy tests are concerned with signal detection.
 213 Indeed, it is possible that the purpose of the test is not to detect a difference
 214 between classes, but to actually test if a particular classifier is better than
 215 chance. This would be the case, for instance, with brain-machine interfaces,
 216 where the detection of a signal is not enough. In such cases, the performance
 217 of a particular classifier is the object of study, rendering the accuracy test
 218 the appropriate choice.

219 Secondly, there may be cases where the accuracy test does have more
 220 power than the location test. Our simulations were unable to point out such
 221 a scenario, but the fact that in our neuroimaging example (Section 5) some
 222 brain regions were detected with the accuracy test, and not the location test,
 223 suggest that the accuracy test does have more power for particular types of
 224 signal. [TODO: signal in scale? heavy tails?]

225 A very important point is the ease of implementation. The need for cross
 226 validation of the accuracy test greatly increases its computational complexity.
 227 Moreover, anyone who has actually implemented tests with discrete statistics,
 228 will attest they are considerably harder to implement. This is because their
 229 unforgiveness to the type of inequality. Indeed, replacing a weak inequality
 230 with a strong inequality may considerably change the results. This is not the
 231 case for continuous test statistics.

232 Given all the above, we find the popularity of accuracy tests quite puz-
 233 zling. We believe this is due to a reversal of the inference cascade. Re-
 234 searchers first fit a classifier, and then ask if the classes are any different.
 235 Were they to start by asking if classes are any different, and only then try to
 236 classify, then location tests would naturally arise as the preferred method.

288 A Analysis pipeline

289 Here is the analysis pipeline of Stelzer et al. [2013] we for the auditory data in
 290 Gilron et al. [2016]. Denoting by $i = 1, \dots, I$ the subject index, $v = 1, \dots, V$
 291 the voxel index, and $s = 1, \dots, S$ the permutation index. Since regions³ are
 292 centred around a unique voxel, the voxel index v also serves as a unique
 293 region index. Algorithm 1 computes a region-wise test statistic, which is
 294 compared to its permutation null distribution computed by Algorithm 2.

Algorithm 1: Compute a group parametric map.

Data: fMRI scans, and experimental design.
Result: Brain map of group statistics: $\{\bar{T}_v\}_{v=1}^V$

```

1 for  $v \in 1, \dots, V$  do
2   for  $i \in 1, \dots, I$  do
3      $T_{i,v} \leftarrow$  test statistic for subject  $i$  in a region centered at  $v$ .
4    $\bar{T}_v \leftarrow \frac{1}{I} \sum_{i=1}^I T_{i,v}$ .
```

Algorithm 2: Compute a permutation p-value map.

Data: fMRI scans of 20 subjects, experimental design.
Result: Brain map of permutation p-values: $\{p_v\}_{v=1}^V$

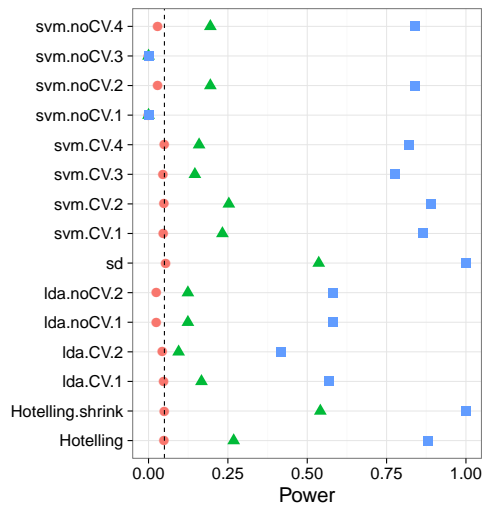

```

1 for  $s \in 1, \dots, S$  do
2   permute labels;
3    $\bar{T}_v^s \leftarrow$  parametric map
```

³*searchlight* or *sphere* in the MVPA parlance
